# Outline

Markov decision process

Markov decision problem

Examples

## Markov decision process

- ▶ add **input** (or **action** or **control**) to Markov chain with costs
- ▶ input selects from a set of possible transition probabilities
- ▶ input is function of state (in standard information pattern)

## Definition: Dynamical system form

$$x_{t+1} = f_t(x_t, u_t, w_t), \quad t = 0, 1, \dots, T - 1$$

- ▶ state  $x_t \in \mathcal{X}$
- ▶ action or input  $u_t \in \mathcal{U}$
- ▶ uncertainty or disturbance  $w_t \in \mathcal{W}$
- ▶ dynamics functions  $f_t : \mathcal{X} \times \mathcal{U} \times \mathcal{W} \rightarrow \mathcal{X}$
- ▶  $x_0, w_0, \dots, w_{T-1}$  are independent RVs
- ▶ variation (state dependent input space):  $u_t \in \mathcal{U}_t(x_t) \subseteq \mathcal{U}$   
( $\mathcal{U}_t(x_t)$  is set of allowed actions in state  $x_t$  at time  $t$ )

## Policy

- ▶ action is function of state:

$$u_t = \mu_t(x_t), \quad t = 0, \dots, T - 1$$

- ▶  $\mu_t : \mathcal{X} \rightarrow \mathcal{U}$  is state feedback function at time  $t$
- ▶  $\mu = (\mu_0, \dots, \mu_{T-1})$  is the policy (or control law)
  
- ▶ number of possible policies:  $|\mathcal{U}|^{|\mathcal{X}|T}$ 
  - ▶ very large for any case of interest
  - ▶ for each  $t = 0, \dots, T - 1$ , for each  $x \in \mathcal{X}$ , we can choose  $\mu_t(x) \in \mathcal{U}$

## Closed-loop system

- ▶ with policy, ('closed-loop') dynamics is

$$\mathbf{x}_{t+1} = F_t(\mathbf{x}_t, \mathbf{w}_t) = f_t(\mathbf{x}_t, \mu_t(\mathbf{x}_t), \mathbf{w}_t), \quad t = 0, 1, \dots, T - 1$$

- ▶  $F_t$  are closed-loop state transition functions
- ▶  $\mathbf{x}_0, \dots, \mathbf{x}_T$  is Markov

## Information patterns

- ▶  $u_t = \mu_t(x_t)$  is standard information pattern
  - ▶ action is function of current state
  - ▶ also called state feedback control
- ▶ some nonstandard information patterns:
  - ▶ full information (or prescient):  $u_t = \mu_t(x_0, w_0, \dots, w_{T-1})$
  - ▶ no information:  $u_t = \mu_t()$  (i.e.,  $u_0, \dots, u_{T-1}$  are fixed)
  - ▶ initial state (also called open-loop):  $u_t = \mu_t(x_0)$
  - ▶ state and disturbance:  $u_t = \mu_t(x_t, w_t)$

## Cost function

- ▶ total cost is

$$J = \mathbf{E} \left( \sum_{t=0}^{T-1} g_t(x_t, u_t, w_t) + g_T(x_T) \right)$$

- ▶ stage cost functions  $g_t : \mathcal{X} \times \mathcal{U} \times \mathcal{W} \rightarrow \mathbf{R}$
- ▶ terminal cost function  $g_T : \mathcal{X} \rightarrow \mathbf{R}$
- ▶ variation: allow  $g_t$  to take on value  $+\infty$  to encode constraints on state-action pairs ( $-\infty$  for rewards, when we maximize)
- ▶ we sometimes write  $J^\mu$  to show dependence of cost on policy

## Closed-loop stage cost functions

- ▶ closed-loop stage cost functions:

$$G_t(x) = \mathbf{E}_{w_t} g_t(x, \mu_t(x), w_t), \quad t = 0, \dots, T - 1$$

(note that  $x_t \perp\!\!\!\perp w_t$ )

- ▶ closed-loop terminal cost function:

$$G_T(x) = g_T(x)$$

## Cost function: Special cases

- ▶ deterministic cost:  $g_t$  do not depend on  $w_t$
- ▶ time-invariant:  $g_0, \dots, g_T$  are the same
- ▶ terminal cost only:  $g_0 = \dots = g_{T-1} = 0$
- ▶ state-control separable (deterministic case):

$$g_t(x_t, u_t, w_t) = q_t(x_t) + r_t(u_t)$$

- ▶  $q_t : \mathcal{X} \rightarrow \mathbf{R}$  is state cost function
- ▶  $r_t : \mathcal{U} \rightarrow \mathbf{R}$  is action cost function

## Value iteration to compute cost

- ▶ we can use value iteration to compute  $J$
- ▶ (deterministic cost for simplicity)
- ▶ take  $V_T(x) = g_T(x)$ ,

$$V_t(x) = g_t(x, \mu_t(x)) + \mathbf{E} V_{t+1}(f_t(x, \mu_t(x), w_t)), \quad t = T - 1, \dots, 0$$

(expectation is over  $w_t$ )

- ▶  $J = \pi_0 V_0$
- ▶ computation cost is  $T|\mathcal{X}||\mathcal{W}|$  operations (fewer for sparse transitions)

## Concrete form

- ▶  $\mathcal{X} = \{1, \dots, n\}$ ,  $\mathcal{U} = \{1, \dots, m\}$

- ▶ transition probabilities (time-invariant case) given by

$$P_{ijk} = \mathbf{Prob}(x_{t+1} = j \mid x_t = i, u_t = k)$$

- ▶  $P_{ijk}$  is probability that next state is  $j$ , when current state is  $i$  and control action  $k$  is taken
- ▶  $P$  is 3-D array (often sparse)
- ▶ in state  $i$ , action chooses next state distribution from choices

$$P_{i,\cdot,k} = [P_{i1k} \ \cdots \ P_{ink}], \quad k = 1, \dots, m$$

- ▶ for time-varying case,  $P$  is 4-D array (!!)

## Concrete form

- ▶ stage costs (time-invariant case) given by

$$C_{ijk}, \quad i, j = 1, \dots, n, \quad k = 1, \dots, m$$

- ▶  $C_{ijk}$  is cost when state  $i$  transitions to state  $j$  with action  $k$
- ▶  $C$  is 3-D array (often sparse); can assume that  $C_{ijk} = 0$  when  $P_{ijk} = 0$
- ▶ state-action separable case:  $C_{ijk} = q_i + r_k$

# Outline

Markov decision process

Markov decision problem

Examples

## Markov decision process

- ▶ Markov decision process (MDP) defined by
  - ▶ (action dependent) state transition functions  $f_0, \dots, f_{T-1}$
  - ▶ distributions of  $x_0, w_0, \dots, w_{T-1}$
  - ▶ stage cost functions  $g_0, \dots, g_{T-1}$
  - ▶ terminal cost function  $g_T$
- ▶ policy defined by state feedback functions  $\mu_0, \dots, \mu_{T-1}$
- ▶ combining Markov decision problem with policy, we get closed-loop Markov chain with costs

## Markov decision problem

- ▶ given Markov decision process, cost with policy  $\mu$  is  $J^\mu$
- ▶ Markov decision problem: find a policy  $\mu^*$  that minimizes  $J^\mu$
- ▶ number of possible policies:  $|\mathcal{U}|^{|\mathcal{X}|T}$  (very large for any case of interest)
- ▶ there can be multiple optimal policies
- ▶ we will see how to find an optimal policy next lecture

## Outline

Markov decision process

Markov decision problem

Examples

## Trading

simple trading model for one asset:

- ▶ hold (integer) number of shares  $q_t \in [Q^{\min}, Q^{\max}]$  in period  $t$
- ▶ buy  $u_t$  shares at time  $t$ ,  $u_t \in [Q^{\min} - q_t, Q^{\max} - q_t]$ , so

$$q_{t+1} = q_t + u_t$$

- ▶ price  $p_t \in \{P_1, \dots, P_k\}$  is Markov;  $p_t$  known before  $u_t$  is chosen
- ▶ revenue is  $-u_t p_t - T(u_t) - S((q_t)_-)$ 
  - ▶  $T(u_t) \geq 0$  is transaction cost
  - ▶  $S((q_t)_-) \geq 0$  is shorting cost
- ▶  $q_0 = 0$ ; we require  $q_T = 0$
- ▶ maximize total expected revenue over  $t = 0, \dots, T - 1$

## Trading

MDP model:

- ▶ state is  $x_t = (q_t, p_t)$
- ▶ stage cost is negative revenue
- ▶ terminal cost is  $g_T(0) = 0$ ;  $g_T(q) = \infty$  for  $q \neq 0$
- ▶ (trading) policy gives number of assets to buy (sell) as function of time  $t$ , current holdings  $q_t$ , and price  $p_t$
- ▶ presumably, good policy buys when  $p_t$  is low and sells when  $p_t$  is high

## Variations

how do we handle (model) the following, and what assumptions would we need to make?

- ▶ price movements that depend on  $u_t$  (price impact)
- ▶ imperfect fulfillment (*i.e.*, you might not buy or sell the full amount  $u_t$ )
- ▶ price movements that depend on a 'signal'  $s_t \in \{S_1, \dots, S_r\}$  that you know at time  $t$
